Communicated by C. Brezinski

We show that a fast algorithm for the QR factorization of a Toeplitz or Hankel matrix A is weakly stable in the sense that $R^T R$ is close to $A^T A$. Thus, when the algorithm is used to solve the semi-normal equations $R^T Rx = A^T b$, we obtain a weakly stable method for the solution of a nonsingular Toeplitz or Hankel linear system $Ax = b$. The algorithm also applies to the solution of the full-rank Toeplitz or Hankel least squares problem $\min \|Ax - b\|_2$.

Keywords: Cholesky factorization error analysis, Hankel matrix, least squares, normal equations, orthogonal factorization, QR factorization, semi-normal equations, stability, Toeplitz matrix, weak stability.

Subject classification: Primary 65F25; Secondary 47B35, 65F05, 65F30, 65Y05, 65Y10.

1. Introduction

Toeplitz linear systems arise in many applications, and there are many algorithms which solve nonsingular $n \times n$ Toeplitz systems

$$Ax = b$$

in $O(n^2)$ arithmetic operations [2,12,44,45,49,53,54,64,66,76,77,79,80,84]. Some algorithms are restricted to symmetric systems ($A = A^T$) and others apply to general Toeplitz systems. Because of their recursive nature, most $O(n^2)$ algorithms assume that all leading principal submatrices of A are nonsingular, and break down if this is not the case. These algorithms are generally unstable, because a leading principal submatrix may be poorly conditioned even if A is well conditioned. Thus, stability results often depend on the assumption that A is symmetric positive definite, in which case the leading principal submatrices are at least as well conditioned as A.

Asymptotically faster algorithms exist [1,4,13,20,40,47,57,58]. Sometimes these algorithms are called *superfast* [1]. We avoid this terminology because, even though the algorithms require only $O(n(\log n)^2)$ arithmetic operations, they may be slower than $O(n^2)$ algorithms for $n < 256$ (see [1,20,67]). We prefer the term *asymptotically fast*.

The numerical stability properties of asymptotically fast algorithms are generally either bad [16] or unknown, although some positive partial results have been obtained recently [42]. Attempts to stabilise asymptotically fast algorithms by look-ahead techniques have been made [40], but the look-ahead algorithms are complicated and their worst-case behaviour is unclear. Thus, we do not consider asymptotically fast algorithms further, but restrict our attention to $O(n^2)$ algorithms.

We are concerned with direct methods for the general case, where A is any nonsingular Toeplitz matrix. In this case no $O(n^2)$ algorithm has been proved to be stable. For example, the algorithm of Bareiss [2] has stability properties similar to those of Gaussian elimination without pivoting [9,72,75], so is unstable and breaks down if a leading principal minor vanishes. Several authors have suggested the introduction of pivoting or look-ahead (with block steps) in the Bareiss and Levinson algorithms [18,19,28–30,74,75], and this is often successful in practice, but in the worst case the overhead is $O(n^3)$ operations. The recent algorithms of Heinig [85] and of Gohberg et al. [34] may in some cases be as stable as Gaussian elimination with partial pivoting, but an error analysis [15] indicates that in the worst case the square of the condition number appears in the backward error bound.

In an attempt to achieve stability without pivoting or look-ahead, it is natural to consider algorithms for computing an orthogonal factorization

$$A = QR \tag{1}$$

of A. The first such $O(n^2)$ algorithm was introduced by Sweet [72,73]. Unfortunately, Sweet's algorithm depends on the condition of certain submatrices of A, so is unstable [8,55]. Other $O(n^2)$ algorithms for computing the matrices Q and R or R^{-1} in (1) were given by Bojanczyk et al. [8], Chun et al. [21], Cybenko [23], Luk and Qiao [55,63], and Nagy [59]. To our knowledge none of them has been shown to be stable. In several cases examples show that they are not stable. Unlike the classical $O(n^3)$ Givens or Householder algorithms, the $O(n^2)$ algorithms do not form Q in a numerically stable manner as a product of matrices which are (close to) orthogonal.

Numerical experiments with the algorithm of Bojanczyk, Brent and de Hoog (BBH for short) suggest that the cause of instability is the method for computing the orthogonal matrix Q; the computed upper triangular matrix $\tilde{R}$ is about as good as can be obtained by performing a Cholesky factorization of A^TA, provided the downdates involves in the algorithm are implemented in a certain way (see section 4). This result is proved in section 5. As a consequence, in section 6 we show how the method of semi-normal equations (i.e. the solution of $R^TRx = A^Tb$) can be used to give a weakly stable algorithm for the solution of

general Toeplitz or hankel systems. The result also applies to the solution of full-rank Toeplitz or Hankel least squares problems. For a discussion of the rank-deficient case and a "look-ahead" modification of Cybenko's algorithm, see [43].

In section 2 we introduce some notation and conventions. The concepts of stability and weak stability are defined in section 3. The Cholesky downdating problem, which arises in the BBH algorithm, is discussed in section 4. Numerical results are discussed in section 7, and some conclusions are given in section 8.

If H is a Hankel matrix, and J is the permutation matrix which on premultiplication reverses the order of the rows of a matrix, then JH is Toeplitz. Also, $(JH)^T(JH) = H^TH$. Thus, our results apply equally to Hankel and Toeplitz matrices. Our results might also be extended to more general classes of matrices with a displacement structure [50–52]. For simplicity we restrict our attention to the Toeplitz case.

2. Notation and conventions

Let

$$A = \begin{pmatrix} a_0 & \cdots & a_{n-1} \\ \vdots & \ddots & \vdots \\ a_{1-m} & \cdots & a_{n-m} \end{pmatrix}$$

be a real $m \times n$ Toeplitz matrix, so $a_{i,j} = a_{j-i}$ for $1 \le i \le m$, $1 \le j \le n$. We assume that $m \ge n$ and that A has rank n. Thus A^TA has a Cholesky factorization $A^TA = R^TR$, where R is an upper triangular $n \times n$ matrix. We assume that the diagonal elements of R are positive, so R is unique. Also, $A = QR$, where Q is an $m \times n$ matrix with orthonormal columns.

If the singular values of A are $\sigma_1, \ldots, \sigma_n$, where $\sigma_1 \ge \ldots \ge \sigma_n > 0$, then the spectral condition number of A is

$$\kappa = \kappa_2(A) = \sigma_1/\sigma_n.$$

For convenience in stating the error bounds, we often assume that σ_1 is of order unity, which can be achieved by scaling.

A *displacement operator* $\mathcal{D} : \mathbb{R}^{m \times n} \to \mathbb{R}^{(m-1)\times(n-1)}$ is defined as follows: for any $m \times n$ matrix B, $\mathcal{D}(B) = C$, where C is the $(m-1) \times (n-1)$ matrix with entries $c_{i,j} = b_{i+1,j+1} - b_{i,j}$, $1 \le i < m$, $1 \le j < n$. Note that $\mathcal{D}B = 0$ iff B is Toeplitz.

Let ϵ be the machine precision. In our analysis we neglect terms of order $O(\epsilon^2)$. This can be justified by considering our bounds as asymptotic expansions in the (sufficiently small) parameter ϵ.

It is often convenient to subsume a polynomial in m and/or n into the "O" notation, and indicate this by a subscript. Thus, an error bound of the form

$$\|E\| = O_m(\epsilon)$$

means that

$$\|E\| \leq P(m)\epsilon$$

for some polynomial P and all sufficiently small ϵ. This notation is useful because minor changes in the algorithm or changes in the choice of norm will be absorbed by a change in the polynomial $P(m)$. It is often stated (e.g. by Björck [6]) that *the primary purpose of rounding error analysis is insight*, and insight can be aided by the suppression of superfluous details.[1]

If the error bound depends on κ then this will be mentioned explicitly (e.g. $\|E\| = O_m(\kappa\epsilon)$). The meaning of "sufficiently small" may depend on κ. For example, we may need $\epsilon < 1/\kappa^2$. We distinguish several classes of numerical quantities:

1. Exact values, e.g. input data such as a_i.
2. Computed values, usually indicated by a tilde, e.g. $\tilde{u}_i$.
3. Perturbed values given by error analysis, usually indicated by a hat, e.g. $\hat{a}_{i,j}$, or by the argument ϵ, e.g. $a_{i,j}(\epsilon)$. These are not computed, but the error analysis shows that they exist and gives bounds on their difference from the corresponding exact values. Sometimes the perturbations are of computed quantities, e.g. $u_i(\epsilon)$.

3. Stability and weak stability

In this section we give definitions of stability and weak stability of algorithms for solving linear systems.

Consider algorithms for solving a nonsingular, $n \times n$ linear system $Ax = b$, so $m = n$. There are many definitions of numerical stability in the literature, for example [5,6,9,11,16,22,36,48,56,60,69]. Definitions 1 and 2 below are taken from Bunch [17].

Definition 1
An algorithm for solving linear equations is *stable* for a class of matrices $\mathscr{A}$ if for each A in $\mathscr{A}$ and for each b the computed solution $\tilde{x}$ to $Ax = b$ satisfies $\hat{A}\tilde{x} = \hat{b}$, where $\hat{A}$ is close to A and $\hat{b}$ is close to b.

Definition 1 says that, for stability, the *computed* solution has to be the *exact* solution of a problem which is close to the original problem. This is the classical *backward stability* of Wilkinson [81–83]. We interpret "close" to mean close in the relative sense in some norm, i.e.

$$\|\hat{A} - A\|/\|A\| = O_n(\epsilon), \qquad \|\hat{b} - b\|/\|b\| = O_n(\epsilon). \tag{2}$$

[1] Wilkinson [81] states "... there is a danger that the essential simplicity of the error analysis may be obscured by an excess of detail."

Note that the matrix $\hat{A}$ is not required to be in the class $\mathscr{A}$. For example, $\mathscr{A}$ might be the class of nonsingular Toeplitz matrices, but $\hat{A}$ is not required to be a Toeplitz matrix. If we require $\hat{A} \in \mathscr{A}$ we get what Bunch [17] calls *strong stability*. For a discussion of the difference between stability and strong stability for Toeplitz algorithms, see [46,78].

Stability does not imply that the computed solution $\tilde{x}$ is close to the exact solution x, unless the problem is well-conditioned. Provided $\kappa\epsilon$ is sufficiently small, stability implies that

$$\|\tilde{x} - x\|/\|x\| = O_n(\kappa\epsilon). \tag{3}$$

For more precise results, see Bunch [17] and Wilkinson [81].

As an example, consider the method of Gaussian elimination. Wilkinson [81] shows that

$$\|\hat{A} - A\|/\|A\| = O_n(g\epsilon), \tag{4}$$

where $g = g(n)$ is the "growth factor". g depends on whether partial or complete pivoting is used. In practice g is usually moderate, even for partial pivoting. However, a well-known example shows that $g(n) = 2^{n-1}$ is possible for partial pivoting, and recently it has been shown that examples where $g(n)$ grows exponentially with n may arise in applications, e.g. for linear systems arising from boundary value problems. Even for complete pivoting, it has not been *proved* that $g(n)$ is bounded by a polynomial in n. Wilkinson [81] showed that $g(n) \leq n^{(\log n)/4 + O(1)}$, and Gould [38] recently showed that $g(n) > n$ is possible for $n > 12$; there is still a large gap between these results. Thus, to be sure that Gaussian elimination satisfies definition 1, we must restrict $\mathscr{A}$ to the class of matrices for which g is $O_n(1)$. In practice this is not a problem, because g can easily be checked *a posteriori*.

Although stability is desirable, it is more than we can prove for many useful algorithms. Thus, following Bunch [17], we define the (weaker, but still useful) property of *weak stability*.

Definition 2

An algorithm for solving linear equations is *weakly stable* for a class of matrices $\mathscr{A}$ if for each well-conditioned A in $\mathscr{A}$ and for each b the computed solution $\tilde{x}$ to $Ax = b$ is such that $\|\tilde{x} - x\|/\|x\|$ is small.

In definition 2, we take "small" to mean $O_n(\epsilon)$, and "well-conditioned" to mean that $\kappa(A)$ is $O_n(1)$, i.e. is bounded by a polynomial in n. From (3), stability implies weak stability.

Definition 2 could be criticised for being too vague. For example, it permits an error of order $\kappa^{100}\epsilon$. In practice, when proving that an algorithm satisfies definition 2 we usually prove something stronger. See, for example, equation (40) below.

Define the *residual* $r = A\tilde{x} - b$. It is well-known [82] that

$$\frac{1}{\kappa}\frac{\|r\|}{\|b\|} \leq \frac{\|\tilde{x} - x\|}{\|x\|} \leq \kappa\frac{\|r\|}{\|b\|}. \tag{5}$$

Thus, for well-conditioned A, $\|\tilde{x} - x\|/\|x\|$ is small if and only if $\|r\|/\|b\|$ is small. This observation clearly leads to an alternative definition of weak stability:

Definition 3
An algorithm for solving linear equations is *weakly stable* for a class of matrices $\mathcal{A}$ if for each well-conditioned A in $\mathcal{A}$ and for each b the computed solution $\tilde{x}$ to $Ax = b$ is such that $\|A\tilde{x} - b\|/\|b\|$ is small.

Now consider computation of the Cholesky factor R of A^TA, where A is an $m \times n$ matrix of full rank n. A good $O(mn^2)$ algorithm is to compute the QR factorization

$$A = QR$$

of A using Householder or Givens transformations [36]. It can be shown [82] that the computed matrices $\tilde{Q}$, $\tilde{R}$ satisfy

$$\hat{A} = \hat{Q}\tilde{R}, \tag{6}$$

where $\hat{Q}^T\hat{Q} = I$, $\tilde{Q}$ is close to $\hat{Q}$, and $\hat{A}$ is close to A. Thus, the algorithm is stable in the sense of backward error analysis. Note that $\|A^TA - \tilde{R}^T\tilde{R}\|/\|A^TA\|$ is small, but $\|\tilde{Q} - Q\|$ and $\|\tilde{R} - R\|/\|R\|$ are not necessarily small. Bounds on $\|\tilde{Q} - Q\|$ and $\|\tilde{R} - R\|/\|R\|$ depend on κ, and are discussed in [35,70,83].

A different algorithm is to compute (the upper triangular part of) A^TA, and then compute the Cholesky factorization of A^TA by the usual (stable) algorithm. The computed result $\tilde{R}$ is such that $\tilde{R}^T\tilde{R}$ is close to A^TA. However, this does not imply the existence of $\hat{A}$ and $\hat{Q}$ such that (6) holds (with $\hat{A}$ close to A and some $\hat{Q}$ with $\hat{Q}^T\hat{Q} = I$) unless A is well-conditioned [71]. By analogy with definition 3 above, we may say that Cholesky factorization of A^TA gives a *weakly stable* algorithm for computing R, because the "residual" $A^TA - \tilde{R}^T\tilde{R}$ is small.

4. Cholesky updating and downdating

4.1. *Updating*

The Cholesky updating problem is: given an upper triangular matrix $R \in \mathbb{R}^{n\times n}$ and a vector $x \in \mathbb{R}^n$, find an upper triangular matrix U such that

$$U^TU = R^TR + xx^T. \tag{7}$$

The updating problem can be solved in a numerically stable manner by transforming the matrix $\binom{x^T}{R}$ to upper triangular form $\binom{U}{0^T}$ by applying a sequence of plane rotations on the left. For details, see [36].

4.2. *Downdating*

The Cholesky downdating problem is: given a upper triangular matrix $R \in \mathbb{R}^{n\times n}$ and a vector $x \in \mathbb{R}^n$ such that $R^TR - xx^T$ is positive definite, find an upper

triangular matrix U such that

$$U^T U = R^T R - xx^T. \tag{8}$$

Proceeding formally, we can obtain (8) from (7) by replacing x by ix. However, the numerical properties of the updating and downdating problems are very different. The condition that $R^T R - xx^T$ be positive semi-definite is necessary for the existence of a real U satisfying (8). Thus, we would expect the downdating problem to be ill-conditioned if $R^T R - xx^T$ has small singular values, and Stewart [71] shows that this is true.

There are several algorithms for the Cholesky downdating problem [3,7,10,11, 24,25,32,36,61,65] and we shall not discuss them in detail here. What is relevant to us is the error analysis. To simplify the statement of the error bounds, suppose that $\|R\| = O_n(1)$, which implies that $\|x\| = O_n(1)$. Observe that, in exact arithmetic, there is an orthogonal matrix Q such that

$$\begin{pmatrix} x^T \\ U \end{pmatrix} = Q \begin{pmatrix} R \\ 0^T \end{pmatrix}. \tag{9}$$

Suppose the computed upper triangular matrix is $\tilde{U}$. Stewart [71] shows that, for the "Linpack" algorithm [24],

$$\begin{pmatrix} x^T(\epsilon) \\ \tilde{U}(\epsilon) \end{pmatrix} = Q(\epsilon) \begin{pmatrix} R \\ 0^T \end{pmatrix}, \tag{10}$$

where $Q(\epsilon)$ is an exactly orthogonal matrix,

$$\|x(\epsilon) - x\| = O_n(\epsilon), \tag{11}$$

and

$$\|\tilde{U}(\epsilon) - \tilde{U}\| = O_n(\epsilon). \tag{12}$$

We can regard $x(\epsilon)$ as a (backward) perturbation of the input data x, and $\tilde{U}(\epsilon)$ as a (forward) perturbation of the computed result $\tilde{U}$. Because of this mixture of forward and backward perturbations, a result of this form is sometimes called a "mixed" stability result. If the problem is ill-conditioned, the backward perturbation is more significant than the forward perturbation.

It is important to note that the error analysis does *not* show that the computed matrix $\tilde{U}$ is close to the exact result U, or that $Q(\epsilon)$ is close to Q, unless U is well-conditioned.

A stability result of the same form as (10)–(12) has been established by Bojanczyk et al. [7] for their "Algorithm C". Because Algorithm C computes $\tilde{U}$ one row at a time, several (updates and/or) downdates can be pipelined, which is not the case for the Linpack algorithm.[2]

[2] The recent algorithm of Bischof et al. [3] can also be pipelined, but we do not know if it gives results which satisfy equations (10)–(12) or (13)–(14).

The result (10)–(12) implies that

$$\tilde{U}^T\tilde{U} = R^TR - xx^T + G(\epsilon), \tag{13}$$

where

$$\|G(\epsilon)\| = O_n(\epsilon). \tag{14}$$

Clearly a similar result holds if a sequence of (updates and) downdates is performed, provided that the final and intermediate results are positive definite.

5. A weak stability result for the BBH algorithm

Our main result (theorem 1 below) is that the BBH algorithm computes R about as well as would be expected if the Cholesky factorization of A^TA were computed by the usual (stable) algorithm. More precisely, the computed $\tilde{R}$ satisfies

$$A^TA - \tilde{R}^T\tilde{R} = O_m(\epsilon\|A^TA\|). \tag{15}$$

To avoid having to include $\|A^TA\|$ in the error bounds, we assume for the time being that $\sigma_1(A) = O(1)$.

First consider exact arithmetic. We partition A in two ways:

$$A = \left(\begin{array}{c|c} a_0 & y^T \\ \hline z & A_{-1} \end{array}\right) = \left(\begin{array}{c|c} A_{-1} & \bar{y} \\ \hline \bar{z}^T & a_{n-m} \end{array}\right), \tag{16}$$

where A_{-1} is an $(m-1)\times(n-1)$ Toeplitz matrix,

$$y = (a_1, \ldots, a_{n-1})^T,$$

$$z = (a_{-1}, \ldots, a_{1-m})^T,$$

$$\bar{y} = (a_{n-1}, \ldots, a_{n-m+1})^T,$$

$$\bar{z} = (a_{1-m}, \ldots, a_{n-m-1})^T.$$

Similarly, we partition R in two ways:

$$R = \left(\begin{array}{c|c} r_{1,1} & u^T \\ \hline 0 & R_b \end{array}\right) = \left(\begin{array}{c|c} R_t & \bar{u} \\ \hline 0^T & r_{n,n} \end{array}\right), \tag{17}$$

where R_b and R_t are $(n-1)\times(n-1)$ upper triangular matrices,

$$u = (r_{1,2}, \ldots, r_{1,n})^T,$$

$$\bar{u} = (r_{1,n}, \ldots, r_{n-1,n})^T.$$

From (16),

$$A^TA = \left(\begin{array}{c|c} a_0^2 + z^Tz & a_0y^T + z^TA_{-1} \\ \hline a_0y + A_{-1}^Tz & A_{-1}^TA_{-1} + yy^T \end{array}\right) = \left(\begin{array}{c|c} A_{-1}^TA_{-1} + \bar{z}\bar{z}^T & \vdots \\ \hline \cdots & \cdot \end{array}\right), \tag{18}$$

where the dots indicate entries which are irrelevant for our purposes. Similarly, from (17),

$$R^T R = \left(\begin{array}{c|c} r_{1,1}^2 & r_{1,1}u^T \\ \hline r_{1,1}u & R_b^T R_b + uu^T \end{array}\right) = \left(\begin{array}{c|c} R_t^T R_t & \vdots \\ \hline \cdots & \cdot \end{array}\right), \tag{19}$$

Equating $A^T A$ and $R^T R$, we obtain

$$r_{1,1}^2 = a_0^2 + z^T z, \tag{20}$$

$$r_{1,1}u = a_0 y + A_{-1}^T z, \tag{21}$$

$$A_{-1}^T A_{-1} + yy^T = R_b^T R_b + uu^T, \tag{22}$$

and

$$A_{-1}^T A_{-1} + \bar{z}\bar{z}^T = R_t^T R_t. \tag{23}$$

Eliminating $A_{-1}^T A_{-1}$ from (22)–(23) gives the relation

$$R_b^T R_b = R_t^T R_t + yy^T - uu^T - \bar{z}\bar{z}^T, \tag{24}$$

which is the basis for the BBH algorithm. If R_t were known, then R_b could be computed from (24) using one Cholesky updating step and two Cholesky downdating steps, as discussed in section 4. Also, since updating and downdating algorithms can proceed by rows, knowledge of the first k rows of R_t is sufficient to allow the computation of the first k rows of R_b. It is easy to compute the first row of R from relations (20)–(21). (For future reference, suppose that the computed first row of R is $(\tilde{r}_{1,1}, \tilde{u}^T)$.) It is clear from (17) that the kth row of R_b defines the $(k+1)$th row of R_t. Thus, we can compute R_t and R_b row by row. For details see [8].

A straightforward extension of the result (13)–(14) applies to our problem of computing R_t and R_b. Provided the "Algorithm C" variant of downdating [7] is used, the computed results $\tilde{R}_t$ and $\tilde{R}_b$ satisfy

$$\tilde{R}_b^T \tilde{R}_b = \tilde{R}_t^T \tilde{R}_t + yy^T - \tilde{u}\tilde{u}^T - \bar{z}\bar{z}^T + G(\epsilon), \tag{25}$$

where

$$\|G(\epsilon)\| = O_m(\epsilon). \tag{26}$$

Here y, $\bar{z}$ and $\tilde{u}$ are inputs to the up/downdating procedures ($\tilde{u}$ may differ slightly from the exact u because $\tilde{u}$ has been computed from (20)–(21)). At this point we make no claims about the size of $\|\tilde{R}_b - R_b\|$ and $\|\tilde{R}_t - R_t\|$. All we need is that $\tilde{R}_b$ and $\tilde{R}_t$ exist and are bounded for sufficiently small ϵ.

Because of the algorithm for their computation, the computed matrices $\tilde{R}_t$ and $\tilde{R}_b$ are related so that we can define the "computed R", say $\tilde{R}$, in a consistent manner by

$$\tilde{R} = \left(\begin{array}{c|c} r_{1,1}^2 & \tilde{u}^T \\ \hline 0 & \tilde{R}_b \end{array}\right) = \left(\begin{array}{c|c} \tilde{R}_t & \vdots \\ \hline 0^T & \cdot \end{array}\right). \tag{27}$$

From (27) we have

$$\tilde{R}^T\tilde{R} = \left(\begin{array}{c|c} \tilde{r}_{1,1}^2 & \tilde{r}_{1,1}\tilde{u}^T \\ \hline \vdots & \tilde{R}_b^T\tilde{R}_b + \tilde{u}\tilde{u}^T \end{array}\right) = \left(\begin{array}{c|c} \tilde{R}_t^T\tilde{R}_t & \vdots \\ \hline \cdots & \cdot \end{array}\right). \tag{28}$$

Recall our definition of the operator $\mathscr{D}$ in section 2. From (28) we have

$$\mathscr{D}(\tilde{R}^T\tilde{R}) = \tilde{R}_b^T\tilde{R}_b + \tilde{u}\tilde{u}^T - \tilde{R}_t^T\tilde{R}_t. \tag{29}$$

Thus, from (25),

$$\mathscr{D}(\tilde{R}^T\tilde{R}) = yy^T - \bar{z}\bar{z}^T + G(\epsilon). \tag{30}$$

Also, from (18),

$$\mathscr{D}(A^TA) = yy^T - \bar{z}\bar{z}^T. \tag{31}$$

If $E = \tilde{R}^T\tilde{R} - A^TA$ and $F = \mathscr{D}(E)$ then, from (30)–(31),

$$F = G(\epsilon). \tag{32}$$

If $1 \le j \le i \le n$ then, by the definition of $\mathscr{D}(E)$,

$$e_{i,j} - e_{i-j+1,1} = \sum_{k=1}^{j-1}(e_{i-k+1,j-k+1} - e_{i-k,j-k}) = f_{i-1,j-1} + f_{i-2,j-2} + \cdots + f_{i-j+1,1}.$$

The first row of $\tilde{R}^T\tilde{R}$ is $\tilde{r}_{1,1}(\tilde{r}_{1,1}, \tilde{u}^T)$, which is close to $r_{1,1}(r_{1,1}, u^T)$, so the first row of E has norm $O_m(\epsilon)$. Also, E is symmetric. It follows that

$$\|E\| \le (n-1)\|F\| + O_m(\epsilon) = O_m(\epsilon).$$

Thus, after scaling to remove our assumption that $\sigma_1 = O(1)$, we have proved:

Theorem 1
If the BBH algorithm is used with the downdating steps performed as in "Algorithm C" of [7], then the computed Cholesky factor $\tilde{R}$ of A^TA satisfies

$$\|\tilde{R}^T\tilde{R} - A^TA\| = O_m(\epsilon\|A^TA\|). \tag{33}$$

Since $A^TA = R^TR$, a comparison of the partitioned forms (19) and (28) shows that

$$\|\tilde{R}_b^T\tilde{R}_b - R_b^TR_b\| = O_m(\epsilon\|R^TR\|) \tag{34}$$

and

$$\|\tilde{R}_t^T\tilde{R}_t - R_t^TR_t\| = O_m(\epsilon\|R^TR\|). \tag{35}$$

From (33) and Stewart's perturbation analysis [71], it follows that

$$\|\tilde{R} - R\|/\|R\| = O_m(\kappa\epsilon). \tag{36}$$

Note that the condition number κ appears in (36) but not in (33)–(35).

The importance of performing the downdating steps as in "Algorithm C" of [7] is not clear. There are several variants of downdating which are applicable to Toeplitz QR factorisation [3,7,59,62] and those which we have tried numerically appear to give comparable results. However, the *proof* of theorem 1 depends on the bound (26), which holds for "Algorithm C" but not necessarily for other variants of downdating.

6. The semi-normal equations

Suppose that our aim is to solve a nonsingular $n \times n$ Toeplitz linear system

$$Ax = b, \tag{37}$$

using $O(n^2)$ arithmetic operations. In exact arithmetic, the *normal equations*

$$A^T Ax = A^T b \tag{38}$$

and the *semi-normal equations*

$$R^T Rx = A^T b, \tag{39}$$

where R satisfies (1), are equivalent to (37).

In most circumstances the use of the normal or semi-normal equations is not recommended, because the condition number $\kappa(A^T A)$ may be as large as $\kappa(A)^2$ (see §5.3 of Golub and Van Loan [36]). When A is Toeplitz (but not symmetric positive definite) we can justify use of the semi-normal equations. This is because the usual stable algorithms for solving (37) directly require $O(n^3)$ arithmetic operations, but we can use the algorithm of section 5 to compute (a numerical approximation $\tilde{R}$ to) R in $O(n^2)$ operations, and then solve the seminormal equations (39) in an additional $O(n^2)$ operations.

From theorem 1, we can compute an upper triangular matrix $\tilde{R}$ such that (33) holds. We can also compute an accurate approximation $\tilde{d}$ to $d = A^T b$ in $O(n^2)$ operations (using the obvious algorithm) or in $O(n \log n)$ operations (using the Fast Fourier Transform). Now solve the two triangular systems $\tilde{R}^T w = d$ and $\tilde{R}x = w$. We expect to obtain a result $\tilde{x}$ for which

$$\|\tilde{x} - x\| / \|x\| = O_n(\kappa^2 \epsilon), \tag{40}$$

where $\kappa = \kappa(A)$, provided $\kappa^2 \epsilon \ll 1$. The residual $r = A\tilde{x} - b$ should satisfy

$$\frac{\|r\|}{\|A\| \|x\|} = O_n(\kappa \epsilon), \tag{41}$$

because $\|A^T r\| = \|A^T A\tilde{x} - A^T b\| - O_n(\epsilon \|A^T A\| \|x\|)$. From (40), the method is *weakly stable* (according to definition 2), although we cannot expect the stronger bound (3) to be satisfied.

The bounds (40)–(41) are similar to those usually given for the method of normal equations [36], not those usually given for the method of semi-normal equations

[5,60,65]. This is because, in applications of the semi-normal equations, it is usually assumed that $\tilde{R}$ is computed via an orthogonal factorization of A, so there is a matrix $\hat{A}$ such that $\tilde{R}^T\tilde{R} = \hat{A}^T\hat{A}$ and

$$\|\hat{A} - A\|/\|A\| = O_n(\epsilon). \tag{42}$$

However, in our case we only have $\|\tilde{R}^T\tilde{R} - R^TR\|/\|R^TR\| = O_n(\epsilon)$, which implies the weaker bound

$$\|\hat{A} - A\|/\|A\| = O_n(\kappa\epsilon) \tag{43}$$

by Stewart's perturbation analysis [70,71].

An alternative to the use of (39) was suggested by Paige [60]: compute R such that $R^TR = AA^T$, solve $R^TRw = b$ by solving two triangular systems, then set $x = A^Tw$. We prefer to use (39) because it is also applicable in the rectangular (least squares) case – see section 6.2.

6.1. *Storage requirements*

The algorithm described above for the solution of the semi-normal equations (39) requires working storage $O(n^2)$ words, because the upper triangular matrix R is not Toeplitz. However, it is possible to reduce the storage requirement to $O(n)$ words. Recall that $\tilde{R}$ is generated row by row. Thus, we can solve $\tilde{R}^Tw = d$ as $\tilde{R}$ is generated, accumulating the necessary inner products with $O(n)$ storage. We now have to solve $\tilde{R}x = w$ without having saved $\tilde{R}$. Provided the $O(n)$ rotations defining the updates and downdates have been saved, we can regenerate the rows of $\tilde{R}$ in reverse order $(n, n-1, \ldots, 1)$ and solve $\tilde{R}x = w$ as this is done. A similar idea was used in [14] to save storage in a systolic implementation of the Bareiss algorithm.

The regenerated matrix $\tilde{R}'$ differs slightly from $\tilde{R}$ because of rounding errors. Numerical experiments suggest (though we have not proved) that $\|\tilde{R}' - \tilde{R}\| = O_n(\kappa\epsilon)$. If true, this would imply that the method is weakly stable, and (40) would hold, but the right hand side of (41) would need to be multiplied by κ.

An alternative is to use an idea which was suggested by Griewank [39] in a different context. Suppose we have a procedure $\mathscr{F}(k)$ which generates k consecutive rows of $\tilde{R}$ in a forward direction (say rows $d+1, \ldots, d+k$), and $\mathscr{B}(k)$ which generates k consecutive rows in a backward direction (say rows $d+k, \ldots, d+1$). In each case $O(n)$ words of storage suffice for the initial conditions. Then $\mathscr{B}(2k)$ can be defined recursively:

1. Generate rows $d+1, \ldots, d+k$ using $\mathscr{F}(k)$, with row d for initial conditions if $d > 0$, saving row $d+k$.
2. Generate rows $d+2k, \ldots, d+k+1$ using $\mathscr{B}(k)$ with row $d+k$ for initial conditions.
3. Generate rows $d+k, \ldots, d+1$ using $\mathscr{B}(k)$ with row d for initial conditions if $d > 0$.

From the discussion in section 5, $\mathscr{F}(k)$ requires $O(kn)$ operations and $O(n)$ storage. Thus, we can prove by induction that $\mathscr{B}(k)$ requires $O(kn\log k)$ operations and $O(n\log k)$ storage. Overall, to generate the n rows of $\tilde{R}$ in reverse order takes $O(n^2\log n)$ operations and $O(n\log n)$ storage. Thus, at the cost of a factor $O(\log n)$ in the operation count, we can reduce the storage requirements from $O(n^2)$ to $O(n\log n)$. The numerical properties of this method are exactly the same as those of the method which uses $O(n^2)$ storage, since exactly the same rows of $\tilde{R}$ are computed. The scheme described here is not optimal in its use of storage, but is within a factor of two of the optimal scheme described in [39].

6.2. *Toeplitz least squares problems*

If $A \in \mathbb{R}^{m\times n}$ is Toeplitz with full rank n, then the semi-normal equations (39) may be used to solve the least squares problem

$$\min \|Ax - b\|_2. \tag{44}$$

The use of semi-normal equations for the general full-rank linear least squares problem is discussed in detail by Björck [5], and the only significant difference in our case is that the bound (43) holds instead of (42), so an additional factor κ appears in some of the terms in the error bounds.

6.3. *Operation counts*

We briefly estimate the number of arithmetic operations required by the BBH algorithm and some of its competitors. We assume that the Toeplitz matrix A is real. Some of the operation counts can be reduced by using fast Givens transformations [31,36], but for simplicity we ignore this possibility. We only count multiplications; the number of additions is comparable.

For simplicity, first consider the case $m = n$. In the BBH algorithm, the computation of R takes $7n^2 + O(n)$ multiplications. The computation of $A^T b$ takes n^2 multiplications if done in the obvious way, or $O(n\log n)$ multiplications if the FFT is used. Solving two triangular systems takes $n^2 + O(n)$ multiplications. Thus, to solve a Toeplitz linear system by the method of section 6 takes $9n^2 + O(n)$ multiplications, or $8n^2 + O(n\log n)$ if the FFT is used. This is much cheaper than the $19n^2 + O(n)$ multiplications of the BBH QR factorisation algorithm given in section 3 of [8], which computes Q explicitly. Thus, considering both speed and stability, it is best to avoid the computation of Q.

For the method of Nagy [59], the multiplication count is $16n^2 + O(n)$, and for Cybenko's method [23] it is $23n^2 + O(n)$. The method TpH of [34] requires $21n^2/2 + O(n\log n)$ real multiplications, and the method KGO of [34] requires $13n^2/2 + O(n\log n)$ complex multiplications. Thus, the method of section 6 should be faster than any of these methods, although the methods in [34,85] may be competitive if the Toeplitz matrix A is complex.

For the rectangular case ($m \geq n$), the corresponding multiplication counts (omitting low-order terms and assuming that the FFT is not used) are:

$2mn + 7n^2$ for the method of section 6;

$2mn + 9n^2$ for the method of Nagy [59] using the semi-normal equations;

$2mn + 14n^2$ for the method of Nagy [59] using inverse factorisation (algorithm IF);

$9mn + 14n^2$ for the method of Cybenko [23];

$13mn + 7n^2$ for the method of [8], computing Q explicitly.

For details of the components making up these operation counts, see table 4.1 of [59].

6.4. *Iterative refinement*

Iterative refinement (sometimes called iterative improvement) can be used to improve an approximate solution $\tilde{x}$ to the linear system (37) or the linear least squares problem (44). In practice this gives an accurate solution in a small number of iterations so long as the residual is computed accurately and the working precision is sufficient to ensure convergence [36,37,68,83]. It is not always necessary to use double-precision arithmetic [5,48].

A related idea is to improve the accuracy of $\tilde{R}_b$ and $\tilde{R}_t$ by using Björck's "Corrected Semi-Normal Equations" [5,62] or Foster's scheme of iterative improvement [26]. However, if the aim is simply to solve a linear system, then it is more economical to apply iterative refinement directly to the system.

6.5. *Ill-conditioned problems*

For very ill-conditioned Toeplitz linear systems and least squares problems, it may be desirable to use regularisation, as discussed in section 5 of [59]. We do not consider this here, except to note that our algorithm can easily be modified to compute the Cholesky factorisation of $A^TA + \alpha I$, where α is a positive regularisation parameter. Only small changes in equations (20)–(23) are required.

7. Numerical results

The algorithm described in sections 5 and 6 has been implemented in Pascal on an IBM PC and DEC VAX. In table 1 we give some results for randomly chosen $n \times n$ Toeplitz systems on a DEC VAX with $\epsilon = 2^{-56} \simeq 1.4 \times 10^{-17}$. The elements a_k defining the Toeplitz matrix

$$A = \begin{pmatrix} a_0 & \cdots & a_{n-1} \\ \vdots & \ddots & \vdots \\ a_{1-n} & \cdots & a_0 \end{pmatrix}$$

Table 1
Weakly stable solution of Toeplitz systems.

n	$\mu'\sigma$	$\kappa_1(R)$	e_1	e_2	e_3	e_3^c

200	1.0'2	2.4'4	2.1'2	3.0	2.7	1.4'-1
200	1.0'3	7.9'5	1.4'1	8.2'-2	6.6'-2	5.2'-2
200	1.0'4	5.5'6	2.8'2	6.1'-1	5.0'-1	4.3'-2
200	1.0'5	1.3'8	3.6'2	1.8'-1	3.8'-1	4.3'-2

were chosen from a normal distribution with specified mean μ and standard deviation σ. (The condition number $\kappa(A)$ tends to increase with $|\mu/\sigma|$.) The solution vector x was chosen with normally distributed components (mean 0) and the vector b computed from $b \leftarrow Ax$. A consequence is that $\|x\|/\|b\|$ is unlikely to be large, even if A is poorly conditioned, but this is typical of most applications. Table 1 gives the condition number

$$\kappa_1(R) = \|R\|_1 \cdot \|R^{-1}\|_1,$$

which is a rough approximation to $\kappa_2(R) = \kappa_2(A)$ (the 1-norm was used for computational convenience).

Table 1 gives

$$e_1 = \frac{\|\tilde{R}^T\tilde{R} - A^TA\|_1}{\epsilon\|A^TA\|_1},$$

$$e_2 = \frac{\|\tilde{x} - x\|_2}{\epsilon\kappa_1(R)^2\|x\|_2},$$

$$e_3 = \frac{\|r\|_2}{\epsilon\kappa_1(R)\|A\|_1\|x\|_2},$$

where $r = A\tilde{x} - b$. From theorem 1 and the bounds (40)–(41), we expect these quantities to be bounded by (low degree) polynomials in n. The results confirm this.

For comparison, the last column of table 1 gives e_3^c, the value of the normalised residual e_3 obtained via Cholesky factorization of A^TA. It can be seen that e_3 is not much larger than e_3^c.

We also tried Toeplitz matrices A with some singular principal submatrices (e.g. A with $a_{-1} = a_0 = a_1$). The results were similar to those given in table 1.

8. Conclusion

The method described in section 6 for the solution of general nonsingular Toeplitz or Hankel linear systems[3] requires $O(n^2)$ operations, is weakly stable, and makes no assumption about the conditioning of submatrices of A. We do not know any other methods which have been proved to be stable or weakly stable and have worst-case time bound $O(n^2)$. Algorithms which involve pivoting and/or look-ahead [18,27,41,43,75] may work well in practice, but seem to require worst-case overhead $O(n^3)$ to ensure stability.

Our method should be faster than $O(n^3)$ methods which ignore the Toeplitz structure, even if the working precision has to be increased (i.e. ϵ reduced) in our method to ensure that $\kappa^2\epsilon \ll 1$. Storage requirements are $O(n^2)$, but may be reduced to $O(n \log n)$ or $O(n)$ as discussed in section 6.1.

We have not looked in detail at all the fast Toeplitz QR factorization algorithms mentioned in section 1. It is quite likely that some of these give weakly stable algorithms for the computation of the Cholesky factor R of A^TA, but no proofs have been published.

It remains an open question whether there is a fast Toeplitz QR algorithm which is backward stable for the computation of Q and R (or R^{-1}). Such an algorithm would give a stable algorithm for the solution of $Ax = b$ without recourse to the semi-normal equations.
